Acknowledgements

The Howard T. Odum Florida Springs Institute (FSI) gratefully acknowledges the financial support of the Fish and Wildlife Foundation of Florida, Inc. “Wakulla Springs Baseline Assessment – A Citizen-Science Project” Tag Grant PFS 1516-09 for preparation of this report.

The following individuals volunteered their time to assist FSI staff with baseline data collection: Knox Bagwell, Tanner Dafoe, Paul Donsky, Kathryn Gibson, James Hennessey, Lewis Holcombe, Ryan Kilbride, Debbie Segal, Mackenzie Vecchio, and Robert Williams.

As with collection and analysis of all environmental data, techniques and interpretations may change over time. The raw data collected for this study are available from the Florida Springs Institute upon written request. The Director and staff of the Florida Springs Institute take full responsibility for any errors or omissions in this report.

Section 1.0 Introduction

1.1 Background

Florida's 1,000+ artesian springs are undergoing rapid environmental changes due to a variety of stressors, including reduced discharge, increased nitrate-nitrogen levels, excessive recreation, side effects of aquatic plant management, and structural alterations. These changes result in a shifting ecological baseline for each spring. As the state embarks on comprehensive restoration activities at these springs, there is often little historic data available to assess recovery or continuing decline. The Howard T. Odum Florida Springs Institute (FSI) is embarking on a number of projects to document existing baseline ecological conditions in the springs of Florida. Data collected for these baseline assessments, in combination with ecological data from previous studies will be used to provide a continuing record of changes, both positive and negative, in Florida's endangered springs and spring runs.

Wakulla Spring is one of the largest first-magnitude artesian springs in Florida and in the United States. Wakulla Spring lies within the Edward Ball Wakulla Springs State Park. Wakulla Springs State Park and Lodge are listed on the Natural Register of Historic Places and are a designated National Natural Landmark. A section of the Wakulla Spring run ecosystem, approximately 5.5 miles downstream of Wakulla Spring (upstream of U.S. Highway 98), has received limited previous scientific study and was utilized for this springs baseline assessment project (Figure 1). Wakulla Spring forms the headwaters of the Wakulla River which is nearly 11 miles long to where it merges with the St. Marks River at St. Marks, Wakulla County.

Wakulla Springs Baseline Assessment

Figure 1. Wakulla River Ecosystem Baseline Project location

Section 2.0 Methods

2.1 Introduction

Florida's springs and spring runs are composed of a diverse and interconnected ecosystem of physical, chemical, and biological components. While most biological systems vary considerably due to seasonal changes in sunlight, temperature, and precipitation, this variation is greatly reduced in spring-fed aquatic ecosystems due to their groundwater supply. These natural groundwater discharges demonstrate relatively consistent water temperature, inflow volume, and water chemistry (Odum 1957; Knight 2015). The one major environmental factor that is seasonally variable in springs is the input of solar energy. This seasonal variability must be considered in springs data collection and analysis.

Spring ecosystem data collection occurred over two, 2-week periods (October 19-30, 2015; March 7-17, 2016) and included as many environmental variables as practical. The following ecological metrics were measured in the 1.4-mile long Wakulla River Segment that was the location of this ecosystem baseline assessment (Figure 2):

Physical Environment

- Insolation and photosynthetically active radiation (PAR) and underwater light transmission of PAR
- Stream discharge (water level and flow) and stream velocity
- Secchi disk visibility
- Segment morphometry (water surface area, water depth, and water volume)
- Water quality field parameters (temperature, pH, dissolved oxygen, conductance)

Water Chemistry

- Water chemistry (total Kjeldahl nitrogen [TKN], nitrate+nitrite nitrogen [NO_x-N], and ammonia nitrogen [NH₄-N]. Total nitrogen [TN] and organic nitrogen [ON] were calculated.)

Biology

- Plant community characterization (species, coverage)
- Macrofauna observations (species and counts for emerging insects, snails, turtles, birds, and mammals)
- Human uses

Ecosystem Level

- Ecosystem metabolism metrics (gross primary productivity [GPP], net primary productivity [NPP], community respiration [CR], P/R ratio, and ecological efficiency)
- Nutrient assimilation
- Community export (fine particulate export)

Wakulla Springs Baseline Assessment

2.2 Physical Environment

2.2.1 Underwater Light Transmission

Photosynthetically Active Radiation (PAR) underwater light transmission and attenuation coefficients were measured within the study segment at WK-1, WK-2, and WK-3 in the Wakulla River (Figure 2) using LI-COR brand sensors; LI-200SA (surface quantum sensor), and LI-192 (underwater quantum sensor). Figure 3 provides a typical light sensor installation. A LI-200SA sensor was used to measure PAR energy reaching the water surface, while an underwater LI-COR LI-192 sensor was used to measure PAR energy at multiple water depths. The underwater PAR sensor was attached to a weighted frame and readings were logged at 15 to 30 cm (0.5 to 1 ft) depth intervals from the surface to the bottom of the water column. Measurements at each depth were collected following at least a ten second stabilization period. Light extinction (attenuation) coefficients were calculated from these data using the Lambert-Beer equation (Wetzel 2001):

$$I_z = I_0(e^{-kz})$$

Where:

I_z = PAR at depth z

I_0 = PAR at the water surface

k = diffuse attenuation coefficient, m^{-1}

z = water depth, m

Figure 3. Underwater LI COR sensor used to measure PAR

2.2.2 Stream Discharge and Current Velocity

Stream discharge and velocity were measured at downstream end of the study segment using the Marsh-McBirney Flo-Mate portable flow meter. A fiberglass tape was stretched across the stream channel at the U.S. Highway 98 bridge (Figure 4) perpendicular to the flow direction, allowing depth and velocity to be measured in approximately 25 evenly-spaced segments. At water depths less than 2.5 ft, velocity was measured at 0.6 of the water column. For water depths greater than 2.5 ft, velocity was measured at 0.2, 0.6, and 0.8 fractional depths of the water column. For each of the resulting cross-section sub-segments, velocity was multiplied by width and depth to calculate sub-segment discharge. The total discharge was calculated from the cumulative discharge of all cross-section sub-segments.

The USGS also maintains a discharge station upstream of the study segment at Shadeville Road (USGS 2327022, Figure 1). This station was used to estimate daily discharge within the study segment.

Figure 4. Stream discharge measurement collected along a cross-section of the Wakulla River at U.S. Highway 98

2.2.3 Stream Segment Morphometry

Segment depths were measured by use of a boat-mounted recording depth finder linked to the Global Positioning System (GPS). These data were processed using ArcGIS software to extrapolate the wetted surface area and volume of the spring study segment. Nominal hydraulic residence times were calculated in a spreadsheet for the study segment based on these estimated water volumes and the upstream and downstream flow estimates. These data were used to estimate the wetted surface area, mean depth, and water volume of the study segment. Nominal hydraulic residence times were calculated in a spreadsheet for the study segment based on these estimated water volumes and the upstream and downstream flow estimates.

2.2.4 Secchi Disk Visibility

Water clarity was rapidly assessed using Secchi disk visibility, the distance where the disk disappears from sight. In spring systems, this distance is commonly greater than the depth of the water column and Secchi disk visibility must be measured horizontally. Secchi distance was measured with a 20-centimeter diameter black and white disk attached to the end of a tape measure and held below the surface of the water. A skin diver then extended the tape while moving away from the disk until it is no longer visible.

2.2.5 Weather Station

Local area weather (rainfall, air temperature, solar radiation, and evapotranspiration) was estimated using the University of Florida - Florida Automated Weather Network (FAWN, <http://fawn.ifas.ufl.edu/>). The FAWN network includes a total of 44 weather stations throughout Florida reporting weather data at 15-minute increments. The closest FAWN stations to the Wakulla River Study Segment were in Quincy (32 miles) and Monticello (31 miles).

2.2.6 Water Quality

During each 2-week sampling period, field variables (water temperature, dissolved oxygen concentration, oxygen percent saturation, pH, conductivity and specific conductance) were measured and logged at 30 minute intervals using YSI 6920 recording data sondes.

Oxygen data were collected using optical sensors with automated wipers, which improve calibration and reduce instrument drift during deployment. Data sondes were deployed near the middle of the water column at the upstream and downstream ends of the study segment for periods up to 2-weeks (Figure 5). Data sondes were calibrated prior to deployment and subsequent to their retrieval for each sampling period following the manufacturers protocol.

Water chemistry samples were collected at the beginning and end of each study period, at the upstream, midpoint, and downstream stations. Water chemistry samples were collected as sub-surface grabs. A rinsed water collection bottle was used to collect water samples from about 1 foot below the water surface and used to fill acid-preserved sample bottles. Following collection, samples were placed in an ice-filled cooler and delivered to the analytical laboratory for analysis within 24 hours. Water depth and field variables (temperature, dissolved oxygen, pH, and specific conductance) were also recorded during all water chemistry sampling events.

Water chemistry samples were analyzed for TKN, NO_x-N, and NH₄-N by Advanced Environmental Labs, Gainesville FL, (FDOH certified laboratory # E82620).

Figure 5. Image of data sonde housing with holes that allow free movement of water, while the locking cap and cable provide security.

2.3 Biology

2.3.1 Plant Community Characterization

The distribution and percent cover of aquatic plant communities (macroalgae and submerged aquatic vegetation) in the study segment were visually estimated during the baseline sampling events. Aquatic vegetative cover was documented along transects at station T-1 through T-9 in

Wakulla Springs Baseline Assessment

the Wakulla River (Figure 2) using a semi-quantitative visual method. At each station, all aquatic vegetation within a transect-belt extending from shore to shore (perpendicular to flow) was recorded and percent cover estimated. Linear distance by species was estimated by multiplying the percent cover by the transect-belt distance. These data were used to estimate percent cover, frequency, relative cover, and relative frequency. Frequency was based on dividing the transect into 8 equal sized sub-transects. Values by species were summed and averaged to yield an importance value as follows:

$$\text{Linear Cover Distance for Species A} = \sum \text{line intercept distances for Species A (m)}$$

$$\text{Percent Cover} = \frac{\text{Linear cover distance of Species A (m)}}{\text{Total transect distance (m)}} \times 100$$

$$\text{Relative Percent Cover} = \frac{\text{Linear cover distance of Species A (m)}}{\text{Total linear cover distance of all species (m)}} \times 100$$

$$\text{Absolute Frequency} = \frac{\text{Number of subtransects in which Species A occurred}}{\text{Total number of subtransects}}$$

$$\text{Relative Frequency} = \frac{\text{Absolute frequency of Species A}}{\sum \text{absolute frequencies of all species}} \times 100$$

$$\text{Importance Value} = \frac{(\text{Relative Vegetative Cover} + \text{Relative Frequency})}{2}$$

Observed plants were identified to species or lowest practicable taxonomic classification. No quantitative plant biomass samples are collected.

2.3.2 General Faunal Observations

Bird surveys were conducted during each study period on the Wakulla River from Shadeville Road to Highway 98 (Figure 2). Surveys started at the upstream location at sunrise and worked their way downstream with the current in canoe/kayak. All birds observed (visually or audibility) on the spring run and upland areas were counted and identified to species. These data were used to estimate bird population and diversity in the study area.

2.3.3 Adult Aquatic Insects

Aquatic insect species diversity and populations were characterized based on collections of adults as they emerge from the water. Insect emergence was measured through the use of floating pyramidal traps, each with a sampling area of 0.25 m² (Figure 6). The trap design was based on traps used for midge and mosquito sampling from wetland and aquatic environments (Walton et al. 1999). Each trap was constructed of wood and has four sides covered with fiberglass window screen. Flotation was provided by foam “noodles” attached along the bottom wooden supports. The traps work under the premise that insects emerging into the trap generally seek the highest spot and in the process travel through an inverted funnel into a 500 mL jar inverted over the end of the funnel. A total of up to ten traps were deployed at locations along the periphery of the spring run. At each location the substrate was noted. Traps were deployed and the jars containing the emergent insects collected at 24 to 48 hour intervals during

Wakulla Springs Baseline Assessment

each study period. Insect identifications were made to the lowest practical taxonomic level. The number of insects captured in traps was used to calculate emergence rates and extrapolated across the wetted area of the study segment.

Figure 6. Trap used to collect adult aquatic insects as they emerge from the water

2.3.4 Snails

A visual survey for apple snail egg clutches was conducted within the Wakulla River (Figure 2). The number of egg masses and estimated clutch size (number of eggs per clutch) was documented along each shoreline within the study segment.

Figure 7. Apple snail egg clutch example

2.3.5 Fish

Visual surveys of the fish communities were made in the Wakulla River along two areas of the study segment (Figure 2), between T-1 to T-2 (0.9 ac) and T-8 to T-9 (1.1 ac). Surveys of fish communities were made in October 2015 by four to six people using mask and snorkel gear. The fish observers started at an upstream location and worked their way downstream with the current. The spring run segment was partitioned into approximately equal sections from bank-to-bank with one observer observing and counting in each section. Observers noted the fish species or groups of similar species (lowest practical taxonomic level) of all observed fish, and these observations were reported to a data recorder, who followed the observers in a boat. Following each survey, observers estimated the total length (average and range) by fish species. Fish density was calculated for each sub-section by dividing the average number of individuals counted, by the area sampled. Biomass of fish species was estimated using published length-weight relationships (Schneider et al. 2000) and average species total lengths and numbers. Fish assemblage diversity was calculated using the Shannon-Wiener diversity index based on the calculated densities of individual species (Zar 1984).

2.3.6 Turtles

Quantitative monitoring of the aquatic turtle community was conducted on the study segment during each monitoring period. Turtle censuses were conducted during general wildlife surveys by volunteers and incidental observations during other field collection efforts. The aquatic turtle population density was reported as the number of individuals divided by the surface area of the study segment.

2.3.7 Human Use

Detailed observations of human use were made throughout the time that the study segment was visited. These observations were made from the boat ramp located at Highway 98 (Figure 2) for the visible portions of the spring run and surrounding upland areas. The count area is referred to as the “observation area”. Primary water contact activities were categorized as: wading (less than waist deep), bathing (greater than waist deep and less than neck deep), swimming, snorkeling, tubing, canoeing/kayaking, power boating, and fishing. Primary out-of-water activities included: sitting, walking, sunbathing, and nature study.

For each of these activity categories, the counts of all persons within the observation area were made at 15 minute intervals. Individual counts were multiplied by 0.25 hours (15 minutes) to estimate the average person-hours throughout the period of observation. The total human-use during a one-day period, reported in units of person-hours, was estimated as the sum of the 15-minute counts as follows:

$$\sum_{t1}^{t2} no.persons.dt = \text{person-hours}$$

Where:

T = time (hours)

t1 = time (start)

t2 = time (finish)

Person-hour estimates are in turn divided by the total observation interval in hours to estimate an average number of persons involved in in-water and out-of-water activities for each day of observation. Water and upland areas within the zone of observation were estimated from maps and aerial photographs to normalize data on a per-area basis:

Human-Use Density = no. persons/area counted

The resulting data were tabulated and reported as the average number of persons and human-use density (persons per area) basis by activity and location.

2.4 Ecosystem Level Monitoring

2.4.1 Ecosystem Metabolism

Ecosystem metabolism was calculated in the study segment using an Excel spreadsheet adaptation of the upstream/downstream dissolved oxygen (DO) change methods of H.T. Odum (1957a, 1957b). This method estimates and subtracts upstream from downstream DO mass fluxes corrected for atmospheric diffusion to determine the metabolic oxygen rate-of-change of the aquatic ecosystem. Dissolved oxygen mass inputs typically include spring discharges, atmospheric diffusion into the water column (when DO is less than 100% saturation), accretion from other undocumented stream or spring seep inflows, and the release of DO as a by-product of aquatic plant photosynthesis. Oxygen losses include diffusion from the water column to the atmosphere (under super-saturated conditions), the metabolic

Wakulla Springs Baseline Assessment

respiration of the aquatic microbial, plant, and animal communities, and sediment biological oxygen demand.

The downstream DO concentration measured at any time is the net effect of these gains and losses as shown in the following conceptual equation:

$$\Delta \text{DO} = \text{GPP} - \text{CR} + \text{Din} + \text{A}$$

Where:

ΔDO = DO rate-of-change, g O₂/m²/d

GPP = gross primary productivity, g O₂/m²/d

CR = community respiration, g O₂/m²/d

Din = diffusion into the water under unsaturated conditions, g O₂/m²/d

A = accrual of DO from other spring boils, g O₂/m²/d

The DO measurements used to estimate segment ecosystem metabolism were collected at the upstream and downstream end of each study segment at 30 minute intervals using recording YSI 6920 data sondes with optical DO sensors.

Upstream and downstream dissolved oxygen data were each shifted by one-half of the estimated travel time between the upstream and downstream study segment stations and an oxygen rate-of-change curve was prepared. Areas, volumes, current velocities and diffusion measurements were used to estimate ecosystem metabolism. Water surface area was estimated for the study segment using the survey methods described above and corrected hourly using an estimated stage: area relationship. Average velocities were estimated from the stage: volume relationship and spring discharge measurements. Nominal travel times for the water mass were estimated based on the length of the spring run and the estimated hourly current velocities.

This DO rate-of-change curve is corrected for atmospheric diffusion based on measured percent oxygen saturation in the water, and oxygen diffusion rates corrected for water velocity. The corrected oxygen rate-of-change curve for each 24-hour period was used to estimate gross primary productivity (GPP), community respiration (CR), net primary productivity (NPP), production/respiration (P/R) ratio, and ecological efficiency. Figure 8 illustrates these metabolism measurements based on development of a typical oxygen rate-of-change curve.

Descriptions of the ecosystem metabolism parameters follow below:

- Gross primary productivity (GPP) is estimated as the entire area under the oxygen rate-of-change curve, calculated by extending the nighttime corrected oxygen rate-of-change through the daylight hours and estimating the entire area under the daytime curve in g O₂/m²/d. GPP is a measure of all aquatic plant productivity occurring below the water surface within the study segment. GPP includes primary productivity of both algae (including photosynthetic bacteria) and submerged vascular plants.
- Community respiration (CR) is the average of the corrected nighttime oxygen rate-of-change values in g O₂/m²/d. CR is a measure of the total dark metabolism of the entire submerged ecosystem within each study segment. CR includes the respiration of all microbes in the sediments and water column, respiration of bacteria, algae, and

Wakulla Springs Baseline Assessment

- plants in the water column, and respiration of most aquatic animals, including protozoans, macroinvertebrates, crustaceans, and fish. Respiration of turtles, alligators, frogs, snakes, manatees, and other air-breathing aquatic fauna is not included in this calculation.
- Net primary productivity (NPP) is equal to the difference between these two estimates (GPP-CR). NPP provides an estimate of the net fixed carbon that remains each day after the respiratory needs of the aquatic ecosystem are met. CR may be higher than GPP in some streams and during some periods of time, indicating that there are unmeasured inputs of fixed carbon or losses of fixed carbon that were previously stored in the ecosystem.
 - The P/R ratio or ecological quotient is equal to GPP/CR. A P/R ratio of one indicates that production and consumption are equally balanced. A ratio greater than one indicates an autotrophic aquatic ecosystem while a value less than one indicates a heterotrophic ecosystem.
 - Photosynthetic efficiency (PE) is equal to the rate of gross primary productivity divided by the incident PAR during a specified time interval. It estimates the overall efficiency of an aquatic ecosystem to utilize the visible fraction of incident solar radiation, the principal forcing function for autotrophic stream ecosystems. PAR reaching the plant level is estimated based on river stage, the plant community characterization data for segment depth, and the light attenuation coefficient estimated for each sampling event. PE is reported as PAR Efficiency by dividing GPP in $\text{O}_2/\text{m}^2/\text{d}$ by $\text{mol}/\text{m}^2/\text{d}$, resulting in units of $\text{g O}_2/\text{mol}$. PAR Efficiency is also reported as a percentage using the conversion factors employed by Knight (1980; 1983): 4.22 Kcal/g O_2 and 52.27 Kcal/mole of photons (McCree 1972).

Wakulla Springs Baseline Assessment

Figure 8. Example determination of ecosystem metabolism based on upstream-downstream dissolved oxygen data (from WSI 2007).

2.4.2 Nutrient Assimilation

Nutrient assimilation/dissimilation rates for TN, NO_x-N, and NH₄-N were estimated for the study segment by calculating upstream-downstream changes in nutrient mass. Average nutrient mass inputs and outputs were estimated based on average water chemistry concentrations and flows over the period of study. Positive nutrient mass changes indicate assimilation/dissimilation of nutrients, while negative changes indicate an increase in nutrient mass with travel of the spring flow downstream.

2.4.3 Community Export

Community export was measured at both the upstream (WK-1) and downstream (WK-3) end of the study segment to allow an alternative method for estimating net ecosystem production within the segment. Community export of particulate suspended matter was quantified for the study segment using a plankton net suspended in the current at mid-depth (Figure 9). The mesh size on the plankton net was 153 μ m. Three replicate plankton net samples were collected at the upstream and downstream end of each segment. Sample material collected in the plankton net was rinsed into a sample bottle and returned to the laboratory for wet, dry, and ash-free (combusted at an oven temperature of 450 °C) dry weight analyses. As samples were collected, the velocity of the water at the mouth of the net was measured as was the time of net deployment. These data allow calculation of the volume of water passing through the net. The amount of particulate material collected in the net was expressed on a volume and area (based

Wakulla Springs Baseline Assessment

on upstream wetted-area) basis. Particulate export results were reported as dry weight (DW) and ash-free dry weight (AFDW) per upstream area per time ($\text{g DW}/\text{m}^2/\text{d}$ and $\text{g AFDW}/\text{m}^2/\text{d}$, respectively). Overall particulate export for the study segment was calculated as the difference between the upstream and downstream export rates.

Figure 9. Image of plankton net capturing suspended material with flow meter upstream

Section 3.0 Results

3.1 Physical Environment

3.1.1 Underwater Light Transmission

The one major environmental factor that is seasonally variable in springs is the input of solar energy. The influx of light is the most important determinant of overall ecosystem primary productivity in clear-water springs. Light attenuation by dissolved and particulate matter in spring water limits solar energy available to submersed aquatic plants and other primary producers. Figure 10 and Figure 11 provide a summary of the percent transmittance and diffuse attenuation coefficient by station and by monitoring date. Detailed light measurement data are provided in Appendix A.

The percent transmittance between the stations averaged 48.3 percent at 1 m, ranging from 49.3 percent (WK-3) to 50.4 percent (WK-2), while the diffuse attenuation coefficient averaged 0.71 m^{-1} (range 0.69 to 0.74 m^{-1}).

The average percent transmittance for the entire spring run segment varied from 41.7 percent at 1 m (October 30, 2015) to 52.7 percent at 1 m (October 19, 2015), during the two baseline monitoring events. The diffuse attenuation coefficient ranged from 0.65 m^{-1} to 0.88 m^{-1} for the same time period.

Light transmittance values from the study segment were compared to other spring run systems in Florida and were less than average as shown in Figure 12. Light transmittance results from many of these systems were measured just downstream of the main spring vent (WSI 2010). Light transmittance values measured near spring vents generally are higher and show less variability than measurements farther downstream in the spring run. Much of this decline is the direct result of increasing particulate matter, resulting from the release of attached algal cells from plants and sediments with distance downstream. This release of particulate matter in spring runs is the combined result of natural causes like flow velocity and human causes from physical disturbance. The low water clarity documented in this study for the Lower Wakulla River was also the result of increased concentrations of tannic acids (black water) and particulates at the head spring (FSI 2014).

3.1.2 Stream Discharge and Current Velocity

Spring discharge is second only to solar input as one of the most important forcing functions that regulates overall spring habitat support of plant, fish, and wildlife communities. Stream discharge and velocity were measured at the downstream end of the study segment using portable flow meters.

Table 1 provides a summary of discharges measured during the baseline assessment at the downstream ends of the study segment, while Appendix B provides detailed discharge measurements. Stream discharges averaged 863 cfs and 921 cfs during the October 2015 and March 2016 events, respectively. Flow in this section of the Wakulla River was observed to be highly affected by the tide. Daily average discharge measured upstream from USGS 2327022 (Shadeville Road) is included in Table 1 for comparison.

Wakulla Springs Baseline Assessment

Figure 10. PAR percent transmittance (@ 1m) and diffuse attenuation coefficient estimates by station

Wakulla Springs Baseline Assessment

Figure 11. Average PAR percent transmittance (@ 1m) and diffuse attenuation coefficient estimates by monitoring date

Wakulla Springs Baseline Assessment

Figure 12. Average PAR percent transmittance (@ 1m) for Florida spring runs

Discharge was also measured at Sulphur Springs #1 (Figure 2) where it enters the Wakulla River in October 2016. This spring was found to contribute about 1.1 cfs.

Figure 13 provide summaries of average daily discharges along the Wakulla River for USGS 02327022 at Shadeville Road. Stream discharges averaged 708 cfs (range 201 cfs to 3,390 cfs) since 2004 displaying a marked increase over recent decades. The long-term median discharge of Wakulla Springs for the period-of-record from February 1907 until November 2007 was 344 cfs (FSI 2014). The recent discharge data indicate that average flows have more than doubled.

Table 1. Wakulla River flow measurements

Date	Station	Width (ft)	Avg. Depth (ft)	Discharge (cfs)	USGS 02327022 (cfs)

3.1.3 Stream Segment Morphometry

Table 2 summarizes segment wetted area and volume relative to water elevation, estimated from depth data collected within the study segment (Figure 14) with stage area/volume curves provided in Figure 15.

The average wetted surface area and volume of the study segment during the study was 154,626 ft² (38.2 ac) and 18,236,019 ft³ (419 ac-ft), respectively. Nominal hydraulic residence time was estimated at 5.6 hours based on this estimated water volume and an average flow of 903 cfs during this period.

Table 2. Wakulla River stage - area / volume relationship (October 2015) for the study segment sampled during this baseline assessment

Water Depth (ft)	Area		Volume	
	(ac)	(ft ²)	(ac-ft)	(ft ³)
16	38.2	154,626	419	18,236,019
14	37.5	151,898	342	14,910,399

Wakulla Springs Baseline Assessment

Figure 15. Wakulla River Study Segment stage area / volume curves – October 2015

3.1.4 Secchi Disk Visibility

Horizontal Secchi disk visibility measurements were collected on multiple dates at the upstream (WK-1), midpoint (WK-2), and downstream (WK-3) stations (Table 3). These measurements provide additional information concerning water clarity and the light attenuation properties of the spring run. Secchi disk visibility generally remained stable from upstream to downstream with an average difference of only 0.3 feet between WK-1 and WK-3.

Historically, water clarity in the Wakulla River has been variable due to inputs of tannic and high chlorophyll waters (FSI 2014). WSI (2010) reported Secchi disk readings of 9.2 feet in the Wakulla Spring pool in April 2009, while typical horizontal Secchi disk readings from other spring systems ranged from 200 to 300 feet.

Table 3. Horizontal Secchi Disk (ft) measurements in the Wakulla River

Date	WK-1	WK-2	WK-3
10/5/2015	13.1	10.5	---
10/19/2015	17.1	14.1	13.1
10/29/2015	13.1	12.1	17.1
10/30/2015	14.4	16.1	12.1
3/7/2016	17.1	6.9	17.1
3/17/2016	---	11.2	---
Average	15.1	11.8	14.8

3.1.5 Weather Station

Table 4 provides a monthly summary for air temperature, rainfall, solar radiation, and evapotranspiration during the study period.

Table 4. Weather Summary – University of Florida FAWN Quincy and Monticello Stations

Parameter	Stats	October 2015	March 2016
Air Temperature (C)	Average	68.3	63.1
	Min	45.3	33.1
	Max	91.2	86.3
Rainfall (in)	Total	0.44	4.57
Solar Radiation (W/m ²)	Average	155.9	179.8
	Max	221.9	271.0
Evapotranspiration (in)	Total	2.75	3.05

Long-term average rainfall in the springshed is about 62 in/yr and has been relatively consistent over the entire period-of-record (Figure 16; FSI 2014).

Wakulla Springs Baseline Assessment

Figure 16. Annual rainfall record for Wakulla Area (1968-2015)

3.1.6 Water Quality

Water quality field parameters and grab samples for water chemistry analyses were collected at upstream (WK-1), midpoint (WK-2), and downstream (WK-3) stations during each 2-week sampling period. These parameters were collected to characterize water quality conditions concurrent with the other intensive sampling.

Wakulla Springs Baseline Assessment

Table 5 provides a summary of average water quality grab sample results. Detailed water quality data are presented in Appendix C

Average TN concentrations decreased from 0.46 mg/L at the upstream station to 0.43 mg/L at the downstream station. The predominant form of nitrogen was NO_x-N with an average low concentration of 0.33 mg/L at the downstream station to an average high concentration of 0.40 mg/L at the upstream station.

Nitrate data from the study segment were compared to other Florida springs as shown in Figure 17. The NFWMD and FDEP have reported nitrate concentration data at Wakulla Spring from 1966 through 2014 (Figure 18). These data show an increase in nitrate at the head spring area from 0.09 mg/L in 1966 to 1.4 mg/L in 1987, with a decrease to 0.45 mg/L in 2014. The City of Tallahassee reduced nitrogen loads in the Wakulla Springshed by eliminating the use of fertilizer, removal of livestock at the Southeast Sprayfield and land application of nitrogen-containing biosolids, and completing treatment plant upgrades. Following these changes, nitrate concentrations in water from the Wakulla Spring vent declined. However, nitrate concentration reductions at Wakulla Spring appear to be at least partially the result of dilution due to increasing discharge at the spring (FSI 2014).

Wakulla Springs Baseline Assessment

Figure 17. Average nitrate nitrogen concentrations in Florida springs (2001-2016)

Wakulla Springs Baseline Assessment

Figure 18. Wakulla Spring annual nitrate concentrations

Dissolved oxygen (DO) increased slightly from the upstream to downstream station in October 2015, while a decrease was observed in March 2015. Water temperature and pH remained relatively unchanged on average, while conductivity showed an increase during the March 2016 period. This increase is presumably due to inputs from Sulphur Springs (Figure 2, Table 6), between the middle (WK-2) and downstream (WK-3) stations. Turbidity was low throughout the Wakulla River segment with average measured values of 0.3 NTU.

Dissolved oxygen data from the study segment were compared to other Florida springs (near the spring vents) as shown in Figure 19.

Table 7 summarizes average field parameter data collected every 30 minutes with the water quality data sondes at the upstream (WK-1) and downstream (WK-3) stations during the baseline monitoring events. Detailed time series plots are presented in Appendix C.

Dissolved oxygen concentrations and pH were observed to vary in a diurnal pattern (Figure 20), showing a rise in concentration during the day due to primary productivity and decreasing concentrations at night as a result of community respiration.

3.2 Biology

3.2.1 Plant Community Characterization

The distribution and percent cover of aquatic plant communities (macroalgae and submerged aquatic vegetation) within the spring run at Wakulla River study area transects (Figure 2) is summarized in Table 9 and Table 10. Detailed aquatic plant data are provided in Appendix D.

A total of 4 plant and algal species or groups were identified at the Wakulla River monitoring transects during the October 2015 monitoring event. These included tape grass (*Vallisneria americana*), filamentous algae, fanwort (*Cabomba caroliniana*), and Southern naiad (*Najas guadalupensis*). Bare sand and mud had an average percent cover of approximately 40 percent, while all aquatic vegetation combined averaged 80 percent. A range of 1 to 4 aquatic vegetation species occurred within the nine vegetation transects.

Table 8. Wakulla River aquatic vegetation summary overall average for the study segment (October 2015).

Scientific Name	Common Name	Total Distance (m)	Cover		Frequency		Importance Value
			%	Relative	Absolute	Relative	
<i>Vallisneria americana</i>	Tape grass	203	36.0	45.1	0.667	26.1	35.6

Algae	Algae	2	20	50		42	80	5	8	25
<i>Cabomba caroliniana</i>	Fanwort	15		30	80	32	15			15
<i>Najas guadalupensis</i>	Southern naiad	10							15	5
<i>Vallisneria americana</i>	Tape grass	10	1			3		55	75	75
		37	21	80	80	77	95	60	98	120

Aquatic vegetation has been surveyed in the Wakulla River and was summarized in the Wakulla Spring Restoration Action Plan (FSI 2014). Findings from two 2003 surveys identified microalgae coverage ranging from 41 to 51 percent near the Wakulla Spring pool area. Aquatic vascular plant coverage from the same area averaged 52 to 70 percent (hydrilla, strap-leaved sagittaria and southern naiad). WSI (2010) reported approximately 85 percent coverage of submersed aquatic vegetation, including benthic algae, in the upper spring run in 2009. The most common plants being hydrilla and tape grass. Historically, problematic aquatic plants (including hydrilla) have been managed in the upper Wakulla River by the state through the use of herbicide applications and mechanical harvesting methods.

3.2.2 General Faunal Observations

Along the spring run and upland areas, there was a total of 57 bird species observed (42 species in October 2015; 46 species in March 2016) [Figure 21]. The most commonly occurring species were the double-crested cormorant, red-winged blackbird, Northern parula, American goldfinch, turkey vulture, and common yellowthroat. Detailed bird survey data are provided in Appendix E.

Figure 22 provides a summary of the number of bird species observed during summer and winter surveys of the middle Wakulla River by FDEP from 1989 to 2015. The average number of bird species observed was 12.7 species with a range from 5 to 33 species.

Wakulla Springs Baseline Assessment

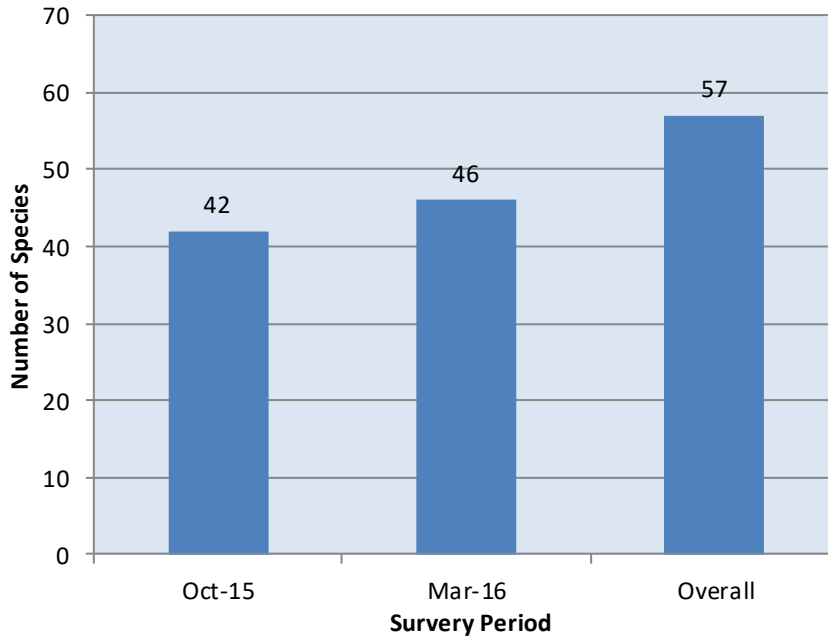

Figure 21. Wakulla River bird survey summary for 2015-2016

Figure 22. FDEP Middle Wakulla River bird survey summary from 1989 to 2015

Wakulla Springs Baseline Assessment

3.2.3 Adult Aquatic Insects

Table 11 presents a summary of adult aquatic insect emergence rates from the Wakulla River spring run study segment. Insect emergence rates averaged 45 organisms/m²/d and 16 organisms/m²/d in October 2015 and March 2016, respectively. This equates to approximately 5,850,200 organisms/day over the study segment area on average. The most commonly collected insects were non-biting midges (*Diptera*), with 80% of the sample belonging to this family.

Figure 23 provides a summary of estimated adult aquatic insect emergence rates compared with other Florida spring run systems studied using the same emergent trap technique, including results from Wakulla Spring in 2009 (WSI 2010). The Wakulla Spring study segment had a lower than average insect emergence rate compared to the other springs studied.

Table 11. Wakulla River adult aquatic insect emergence rates

OrderSuborderFamily			Deployment Date				
			10/19/15	10/29/15	Avg	3/7/16	Avg

Wakulla Springs Baseline Assessment

Figure 23. Wakulla River adult aquatic insect emergence rates compared to other Florida spring runs

3.2.4 Snails

Only one cluster of apple snail eggs was observed during the October 19, 2015 event. None were observed during the March 2016 monitoring periods.

3.2.5 Fish

Table 11 presents the fish survey data from October 2015 with detailed fish data are provided in Appendix F. A total of 4 fish species or groups of similar species were observed during the survey. Fish density and biomass in the Wakulla River spring run study segment averaged 214 fish/ac and 5.3 lbs/ac, respectively (**Error! Reference source not found.**). Minnows (*Notropis s p.*) and sunfish (*Lepomis sp.*) were observed at the highest densities. The Shannon-Wiener diversity index (H') was only 0.27, due to the limited number of species and uneven distribution.

Estimated fish biomass and population densities were compared with other Florida springs studied using the same visual count technique (WSI 2010). Figure 24 visually displays this comparison of the Wakulla River study segment to other Florida springs. For the study segment, the estimated fish densities and biomass were the lowest of the other studied springs.

Wakulla Springs Baseline Assessment

Table 12. Wakulla River fish summary - October 2015

Scientific Name	Common Name	Count	Density (#/ac)	Biomass (lbs/ac)
<i>Lepomis sp.</i>	Sunfish sp.	10	4.91	0.242
<i>Micropterus salmoides</i>	Largemouth Bass	1	0.491	0.016
<i>Notropis sp.</i>	Minnows	420	206	0.750
<i>Mugil cephalus</i>	Striped mullet	5	2.46	4.24
Total		436	214	5.25

Survey Area: T-1 to T-2 (0.89 ac) and T-8 to T-9 (1.14 ac); Total 2.04 ac

Figure 24. Wakulla River fish density and biomass compared to other Florida springs

Wakulla Springs Baseline Assessment

3.2.6 Turtles

On average, an average of 45 individual turtles were observed within the study segment during wildlife surveys (49 in October 2015 and 41 in March 2016). The Suwannee cooter (*Pseudemys coccinea*) were the most common for both survey periods. This resulted in an estimated average turtle population density of 1.2 turtles/ac

Figure 25 provides a summary of turtles surveyed during the summer on the middle Wakulla River by FDEP 1989 to 2015. The average number observed from this period was 110 turtles with a range from 12 to 319.

Figure 25. FDEP Middle Wakulla River turtle summer survey summary from 1989 to 2015

3.2.7 Human Use

Figure 26 provides a summary for total in-water and out-of-water activities at the downstream study segment (Highway 98) in October 2015. Detailed human use survey activities are summarized in Appendix G.

This area of the spring run received higher levels of human activity during the warmer season (October 2015). Due to the low numbers observed during the colder season (March 2016), only incidental observations of human activity were recorded (Appendix G). In October 2015, in-water activities averaged 0.6 people/ac with canoe/kayaking and power boating being the most common activities. Out-of-water activities averaged 0.5 people/ac for the same survey period, with walking and sitting being the most common. Incidental human use activities observed in the study segment during March 2016 included power boating, paddleboard, scuba, and fishing.

Figure 26. Wakulla River human use summary – October 2015

3.3 Ecosystem Level Monitoring

3.3.1 Ecosystem Metabolism

Table 13 provides a summary of ecosystem metabolism parameters collected in the study segment with detailed results in Appendix H. Average GPP ranged from 15.37 g O₂/m²/d (October 2015) to 21.91 g O₂/m²/d (March 2016) over the study period. CR ranged from 13.62 g O₂/m²/d (October 2015) to 22.98 g O₂/m²/d (March 2016), resulting in an average NPP of 2.62 g O₂/m²/d in October 2015, to 0.81 g O₂/m²/d in March 2016. For these data the estimated P/R ratio ranged from 1.06 (March 2016) to 1.29 (October 2015), and the photosynthetic efficiency ranged from 7.81% (or 0.97 g O₂/mol) in March 2016, to 8.70% (or 1.08 g O₂/mol) in October 2015.

Ecosystem metabolism estimates from the study segment were compared to similar data from other Florida springs that have previously been studied (Figure 27). This comparison indicates that the study segment has a high GPP, NPP, and CR compared to other spring systems. When normalized for the amount of incident solar radiation, the study segment was found to have a photosynthetic efficiency above average compared to other Florida springs.

Wakulla Springs Baseline Assessment

Figure 28 and Figure 29 shows the existing data relating photosynthetic efficiency, spring discharge, and NO_x-N concentration for the studied Florida spring systems. The study segment follows the same general relationship observed for other springs. In general, spring photosynthetic efficiency increases with increasing spring discharge (Figure 28), while NO_x-N concentration may have a subsidy-stress effect on photosynthetic efficiency (Figure 29).

Table 13. Rainbow River ecosystem metabolism estimates

Stats	GPP (g O ₂ /m ² /d)	NPP (g O ₂ /m ² /d)	CR (g O ₂ /m ² /d)	P/R Ratio	PAR (24hr) (mol/m ² /d)	PAR Efficiency (%)	PAR Efficiency (g O ₂ /mol)

Wakulla Springs Baseline Assessment

Figure 29. Gross primary productivity efficiency versus NOx-N concentration in Florida springs (based on historic and recent data from a total of 22 springs)

3.3.2 Nutrient Assimilation

Figure 30 provides a summary of the average mass removals in the study segment with details provided in Appendix I. The mass of TN was reduced by an average of 2.5 lbs/ac/d within the study segment with NOx-N being the dominant fraction (6.6 lbs/ac/d). The mass of OrgN increased 5.7 lbs/ac/d, resulting in a TKN increase of 4.8 lbs/ac/d in the study segment. NH₄-N slightly decreased within the study segment (1.6 lbs/ac/d).

Nutrient mass removal data from the study segment were compared to other Florida springs runs as shown Figure 31. This comparison indicates that the study segment mass removal rates are within ranges observed in other Florida spring runs. Average mass removals estimated during this study were very similar to those estimated at the upper Wakulla spring run during 2009, with the exception of OrgN.

Wakulla Springs Baseline Assessment

Figure 30. Wakulla River estimated nutrient mass removals

Wakulla Springs Baseline Assessment

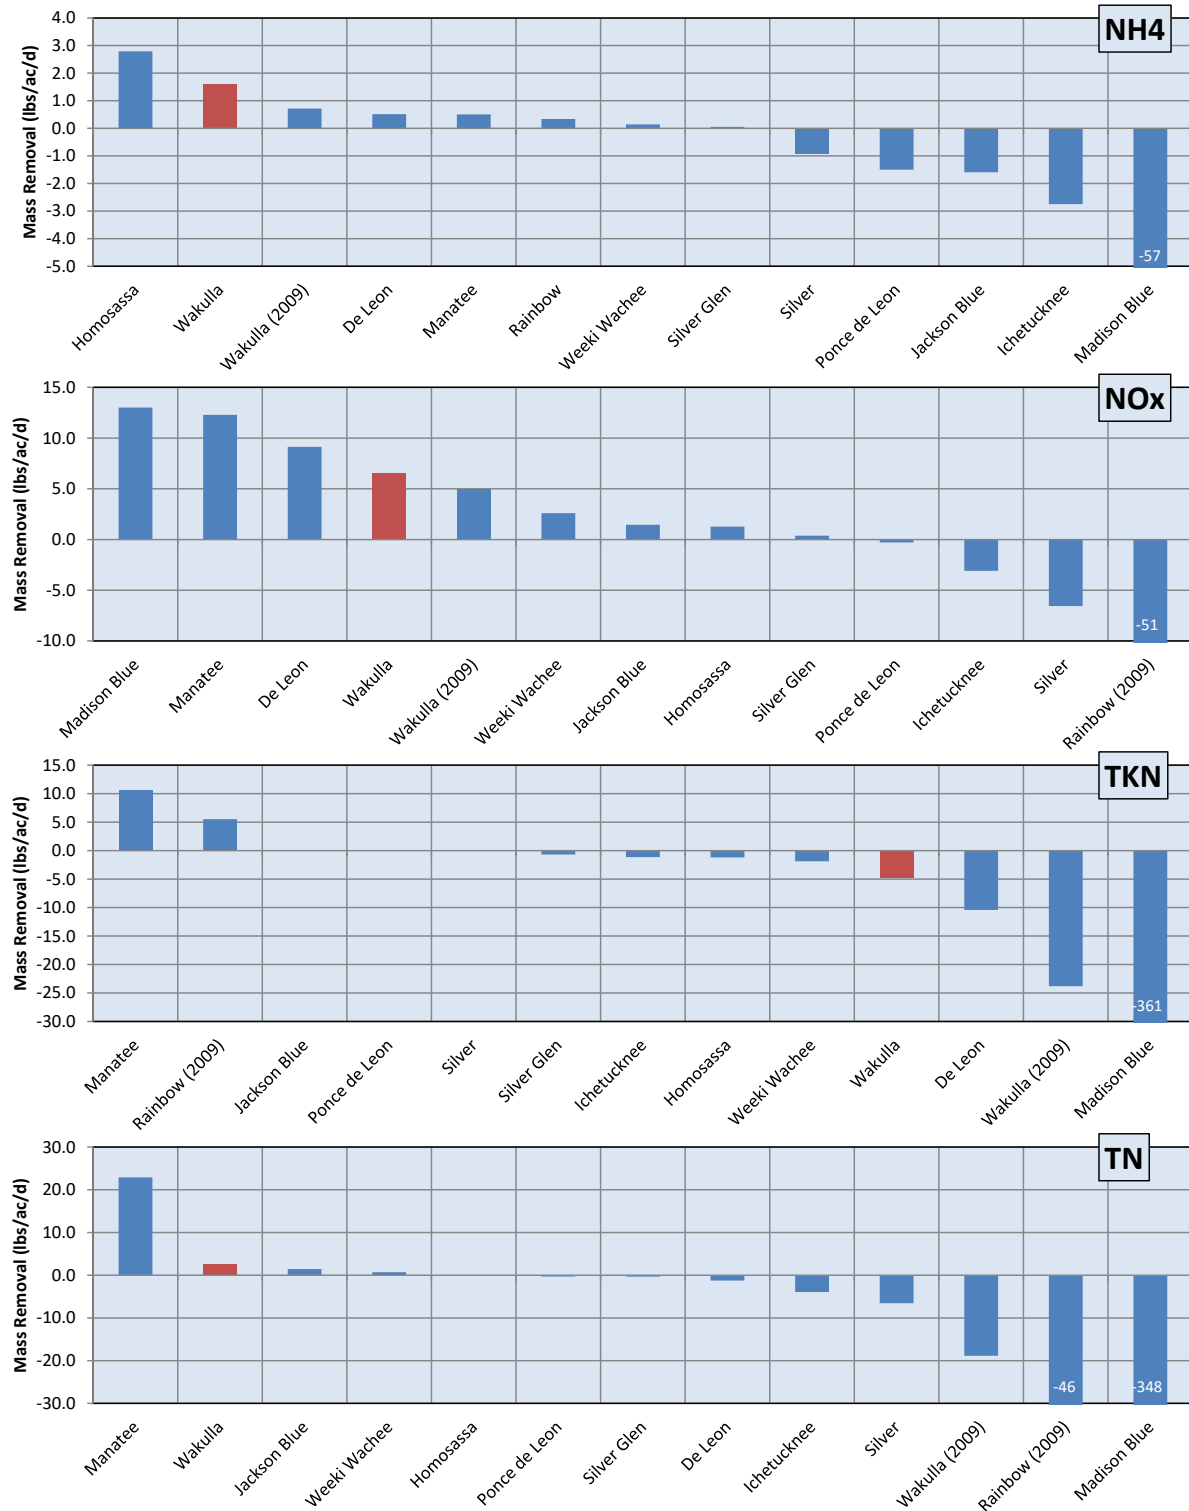

Figure 31. Nutrient mass removals for Florida springs runs

Wakulla Springs Baseline Assessment

3.3.3 Community Export

Community export data for the study segment are summarized in Table 14 with detailed data provided in Appendix J. Segment particulate organic matter export rates varied widely. Positive values indicate a net production of detrital material (material leaving the study segment), while negative values indicate a net accrual of detrital material (material being deposited in the study segment). For October 2015, organic matter export rates were negative for the first event (-0.055 g/m²/d) and positive for the second event (0.146 g/m²/d). The estimated net organic matter export rate was positive for the March 2016 sampling events (0.043 g/m²/d).

Particulate organic matter export data from the study segment were compared to other Florida spring runs as shown Figure 32.

Wakulla Springs Baseline Assessment

Figure 32. Organic material export in Florida spring runs

Section 4.0 Discussion

4.1 Overview

Wakulla Springs is an enigma among Florida's studied springs (FSI 2014). Nitrate levels rose for decades into the 1990s before starting a rapid decline to current levels. Significant public efforts to reduce nitrogen loading to Wakulla Springs began in the past two decades when it was confirmed that anthropogenic loading (primarily from the City of Tallahassee's spray field effluent disposal system) was the dominant source of nitrogen to area groundwaters. In fact, the City's efforts to reduce nitrogen loading from effluent disposal is currently the most expensive "springs restoration" project in the State's history. But, as pointed out by FSI (2014) the spring nitrate concentrations were already declining before the City made significant changes in their treatment process. At the same approximate time, flows from Wakulla Springs were rising, in spite of relatively constant rainfall inputs. Subsequent hydrogeological studies, aided by the unprecedented knowledge about the underground, interconnected cave system feeding groundwater to Wakulla and nearby Springs Creek springs, determined that Wakulla was pirating flows that historically went to its sister spring system on the nearby coast. A more likely explanation of the declining nitrate levels in the Wakulla River is that treatment plant upgrades are being measurably augmented by dilution from low-nitrogen groundwater.

The Wakulla River spring run baseline study segment was about 1.4 miles in length, had a wetted surface area of about 38.2 ac, a water volume of about 419 ac-ft, and an average water depth of 11 ft. The 2015/2016 monitoring data reported during this baseline study from the Wakulla River indicate that this segment is impaired in several respects, and that the ecological structure and function of the spring run is substantially impaired compared to other spring runs. Average flows in the Wakulla River have been increasing since the 1960s. The baseline flows averaged 892 cfs compared to a period-of-record average flow of 344 cfs (an 159% increase). Dissolved oxygen concentrations in the Wakulla River were generally above 5 mg/L with the exception that nighttime summer values dipped down to about 4 mg/L due to high community respiration rates. Measured pH varies around 7.6 standard units, temperature varied between 18 and 20 °C, and specific conductance varied slightly around 329 uS.

Nitrate+nitrite nitrogen concentrations at the springs feeding the Wakulla River averaged about 0.7 mg/L since 2000, about 14 times higher than the assumed background levels of this nutrient (about 0.05 mg/L) and about two times higher than the Florida numeric springs standard of 0.35 mg/L. Measured nitrate concentrations in the lower Wakulla River measured during this baseline study averaged about 0.36 mg/L, partly as a result of natural attenuation by the aquatic ecosystem estimated in this study as 252 lbs/d.

The Wakulla River baseline study segment had low water clarity (horizontal Secchi distance about 13.5 ft) and the water was noticeably colored and turbid. Overall plant and algae cover was estimated as 80% in the shallowest areas and submerged plants were noticeably sparse in the deeper areas of the channel. The cover of filamentous algae in the shallow areas was about 23% and there was a very high load of periphytic algae on eelgrass leaves. Measured

Wakulla Springs Baseline Assessment

populations of insects, snails, turtles, fish, and birds were low in this river segment, indicating poor wildlife habitat support.

Gross ecosystem primary productivity was unusually high (about 19 g/O₂/m²/d), as was community respiration (about 18 g/O₂/m²/d), resulting in very little observed export of useful plant matter. The observed high primary productivity in this aquatic ecosystem appears to be the result of eutrophic nitrogen levels and undesirable changes in the spring run plant communities. Human use of the Wakulla River was low during the week days when sampling was conducted.

The Wakulla River Ecosystem Baseline segment was one of the most impacted spring runs studied by the Florida Springs Institute. Water clarity is very low, indicator species of a healthy spring run such as aquatic insects and mollusks are nearly absent, and populations and diversity of fish and turtles appear to be very low. Routine bird counts upstream in the Wakulla River indicate that populations of several species have declined. On the other hand, community metabolism and photosynthetic efficiency were relatively high compared to other spring runs. On a subsidy-stress curve it appears that the existing combination of elevated nitrate nitrogen and color/turbidity in the river provide a recipe for excessive algae growth and low water clarity. In spite of the regulatory efforts and money expended to-date to restore and protect this river from harm, wildlife habitat functions appears to be seriously impaired compared to other Florida spring runs.

4.2 Wakulla Spring Report Card

The 2016 Wakulla Spring report card is presented in Figure 33 with detailed data provided in Appendix K. The quantitative data assembled for this environmental health assessment indicate that the Wakulla Spring and River system received an average grade. However, the observations of low to very low populations of insects, snails, fish, turtles, and birds in this lower river segment, indicate that the river is impaired for wildlife and food chain support. Additional data collection and analysis will be important to determine the magnitude of any benefits accrued due to the City of Tallahassee's wastewater treatment upgrades.

Appendix K

Wakulla Springs 2016 Report Card

WAKULLA SPRINGS AND RIVER

Spring Discharge	Grade	Average (2012-2016)	A: > 654 cfs B: 493 - 653 cfs C: 364 - 492 cfs D: 290 - 363 cfs F: < 289 cfs
	A	805 cfs	

WAKULLA SPRINGS AND RIVER

Water Clarity @ Spring Run	Grade	Average (2015-2016)	A: > 70 % B: 60 - 69 % C: 50 - 59 % D: 40 - 49 % F: < 40 %
	D	49% Light Transmittance @ 1 meter	

WAKULLA SPRINGS AND RIVER

Nitrate Concentration @ Spring Boil	Grade	Average (2016)	A: < 0.15 mg/L B: 0.15 - 0.35 mg/L C: 0.36 - 0.60 mg/L D: 0.61 - 0.90 mg/L F: > 0.90 mg/L
	C	0.45 mg/L	

WAKULLA SPRINGS AND RIVER

**Adult Aquatic
Emergence @
Spring Run**

Grade

D

**Average
(2015-2016)**

30
insects/m²/day

**A: > 100
B: 75 - 99
C: 50 - 74
D: 25 - 49
F: < 24**

WAKULLA SPRINGS AND RIVER

Fish Biomass	Grade	Average (2016)	A: > 300 B: 200 - 299 C: 100 - 199 D: 50 - 99 F: < 50
	F	5.9 Biomass kg/ha	

WAKULLA SPRINGS AND RIVER

**Photosynthetic
Efficiency**

Grade

B

Average (2015-2016)

5.92 %

A: > 7.0

B: 5.0 - 6.99

C: 3.0 - 4.99

D: 1.0 - 2.99

F: < 1.0
